Understanding SVM Kernels and Their Effect on Decision Boundaries

Objective

The primary goal of this tutorial is to explore the mechanics of **Support Vector Machines (SVMs)** and analyze how different mathematical kernels—**Linear, Polynomial, and Radial Basis Function (RBF)**—influence the shape and flexibility of decision boundaries.

Specifically, we will:

1. **Baseline Test:** Use the **Iris Dataset** (Petal length/width, Setosa vs. Versicolor) to observe standard kernel behavior.
2. **Challenge Case:** Introduce the **Moons Dataset** to demonstrate why non-linear kernels (RBF) are essential when data is geometrically entangled and not linearly separable.
3. **Quantitative Analysis:** Compare model performance using accuracy metrics to prove that "visual fit" aligns with statistical success.

Dataset Overview

- **Iris Dataset:** 100 samples, 2 features. Historically used for linear classification.
- **Moons Dataset:** A synthetic dataset consisting of two interleaving half-circles, used to stress-test non-linear classifiers.

In [47]:
```
import numpy
import matplotlib
import sklearn

print("All libraries imported successfully!")
```

```
All libraries imported successfully!
```

In [48]:
```
import numpy as np
import matplotlib.pyplot as plt
from sklearn import datasets
from sklearn.svm import SVC
from sklearn.preprocessing import StandardScaler
from sklearn.model_selection import train_test_split
from mpl_toolkits.mplot3d import Axes3D
from matplotlib import cm

# Set plots to be PDF-friendly
plt.rcParams["figure.figsize"] = (6,4)
plt.rcParams["figure.dpi"] = 120
```

In [49]:
```
# Load Iris dataset
iris = datasets.load_iris()
X = iris.data[:, 2:4]  # petal length & width
```

```
y = iris.target

# Only use two classes (Setosa and Versicolor)
X = X[y != 2]
y = y[y != 2]

print("Dataset shape:", X.shape)
print("Classes:", np.unique(y))
```

```
Dataset shape: (100, 2)
Classes: [0 1]
```

Dataset

- We are using the Iris dataset with 150 samples.
- For visualization, we focus on **petal length** and **petal width**, and only **2 classes** (Setosa and Versicolor) for simplicity.
- This allows us to plot decision boundaries in 2D.

The Mechanics: Margin Maximization and Support Vectors

[cite_start]The goal of an SVM is not just to find any line that separates classes, but to find the **Maximum Margin Hyperplane**[cite: 193].

- **The Margin:** This is the distance between the decision boundary and the closest data points from either class. [cite_start]A larger margin typically leads to better generalization on unseen data[cite: 184].
- [cite_start]**Support Vectors:** These are the critical data points that lie closest to the decision boundary[cite: 193]. If you move these points, the boundary moves; if you move any other points, the boundary remains the same. They "support" the hyperplane.
- **Regularization (C):** This parameter controls the trade-off between a smooth decision boundary and classifying training points correctly. [cite_start]A **high** C aims for zero misclassification (hard margin), while a **low** C allows for some "slack" (soft margin) to achieve better generalization[cite: 194].

Support Vector Machines (SVM) and Kernels

Linear Kernel

- Separates classes using a straight line (hyperplane)
- Works well if data is linearly separable

Polynomial Kernel

- Creates curved decision boundaries
- Formula: (K(x_i, x_j) = (x_i \cdot x_j + 1)^d)
- `d` is the degree of the polynomial

RBF (Gaussian) Kernel

- Maps data to higher-dimensional space
- Formula: (K(x_i, x_j) = \exp(-\gamma ||x_i - x_j||^2))
- High gamma → tighter curves around points

Kernel Trick and Higher-Dimensional Mapping

SVMs can separate non-linear data by implicitly mapping it into a higher-dimensional space.

- The **Kernel Trick** computes inner products in this space directly, without explicitly transforming the data.
- **Mercer's Theorem** ensures valid kernels correspond to dot products in some feature space.
- Using the **Lagrangian Dual problem**, we optimize in terms of the kernel, allowing non-linear separation efficiently.

In [50]:
```
# Split dataset
X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.2, random_

# Standardize features
scaler = StandardScaler()
X_train = scaler.fit_transform(X_train)
X_test = scaler.transform(X_test)
```

In [51]:
```
def plot_decision_boundary(model, X, y, title):
    # Setup grid for plotting
    x_min, x_max = X[:, 0].min() - 1, X[:, 0].max() + 1
    y_min, y_max = X[:, 1].min() - 1, X[:, 1].max() + 1
    xx, yy = np.meshgrid(np.arange(x_min, x_max, 0.02),
                         np.arange(y_min, y_max, 0.02))

    # Predict over grid
    Z = model.predict(np.c_[xx.ravel(), yy.ravel()])
    Z = Z.reshape(xx.shape)

    # Create the plot
    plt.figure(figsize=(6, 4))
    plt.contourf(xx, yy, Z, alpha=0.3, cmap='viridis')  # Color-blind friendly p
    scatter = plt.scatter(X[:, 0], X[:, 1], c=y, s=50, cmap='viridis', edgecolor

    # Accessibility: Clear labels and titles
    plt.xlabel('Petal Length (Standardized)')
    plt.ylabel('Petal Width (Standardized)')
    plt.title(title)

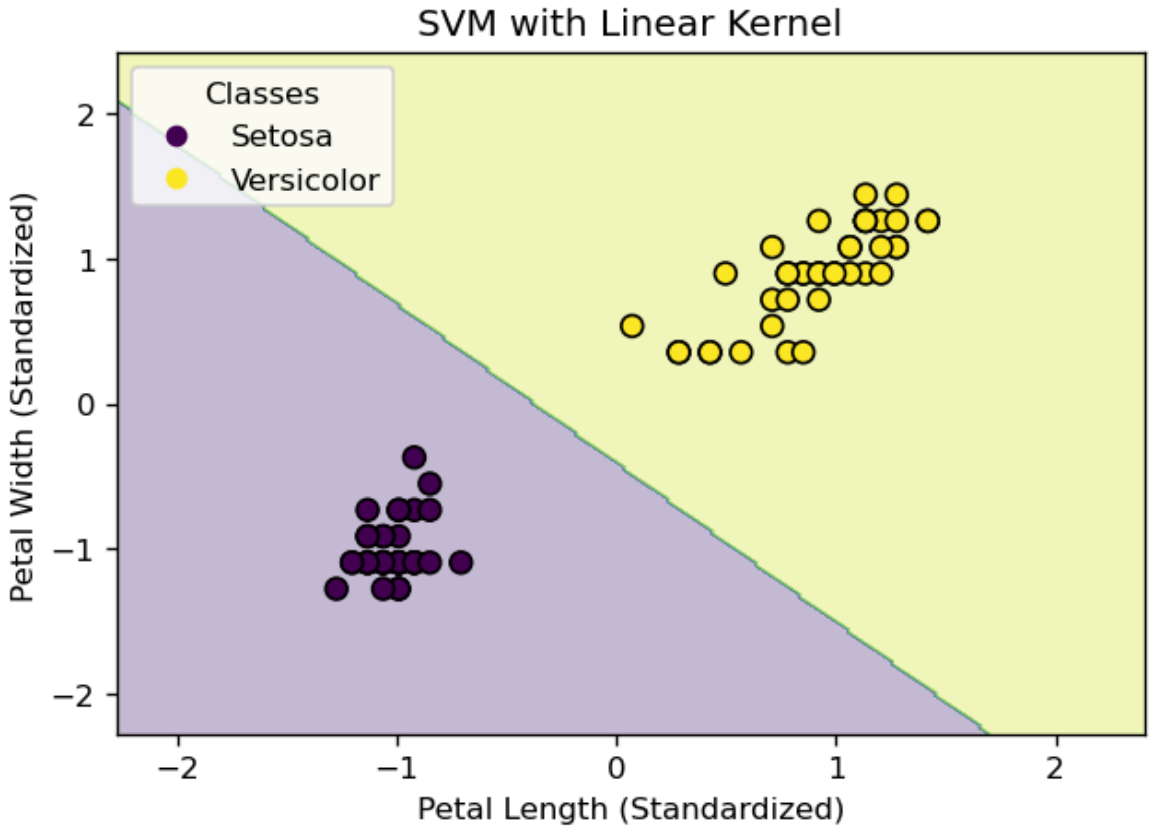
    # Add a legend for clarity
    handles, _ = scatter.legend_elements()
    plt.legend(handles, ['Setosa', 'Versicolor'], title="Classes")

    plt.show()
```

Why Linear SVM?

- We start with a linear kernel to show how SVM separates linearly separable data.
- This establishes a baseline before exploring more complex kernels.

In [52]:
```
linear_model = SVC(kernel='linear', C=1.0)
linear_model.fit(X_train, y_train)
plot_decision_boundary(linear_model, X_train, y_train, "SVM with Linear Kernel")
```

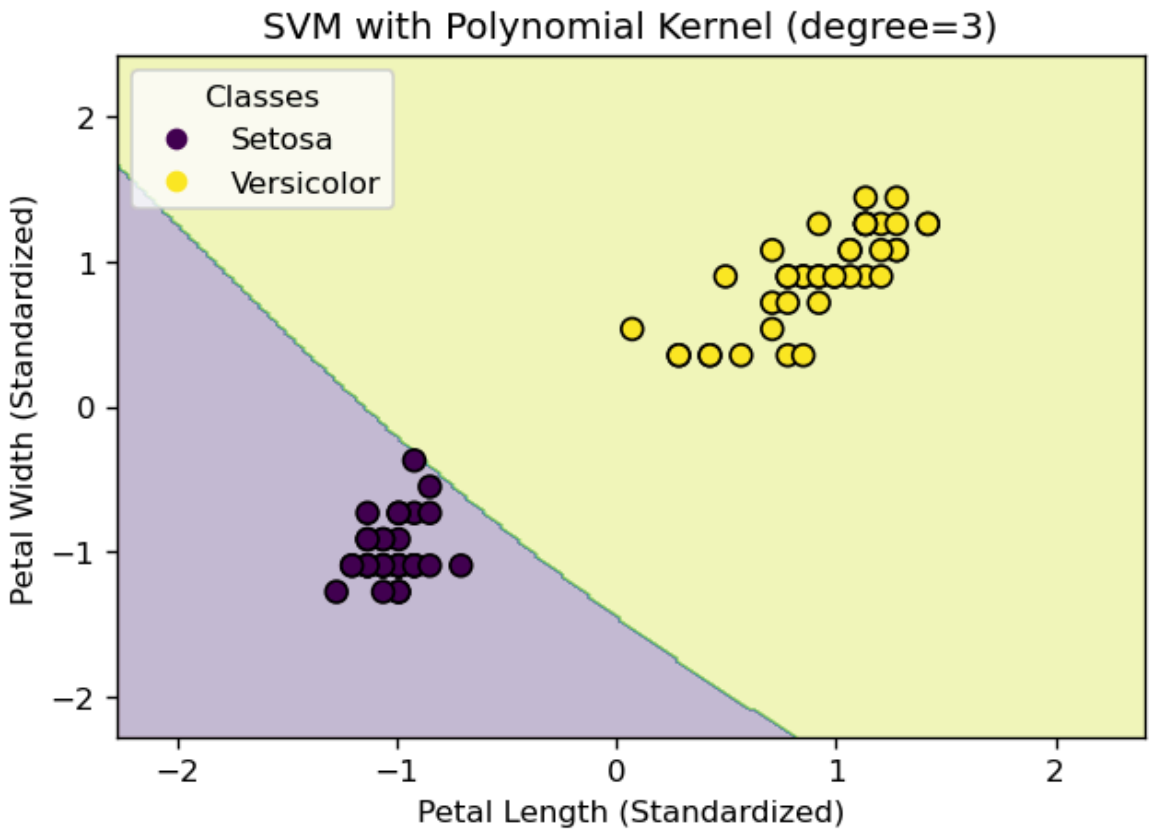


> **Visual Description:** This plot illustrates a **Linear SVM** decision boundary. It shows a perfectly straight diagonal line separating two clusters of data points: purple dots (Setosa) in the bottom-left and yellow dots (Versicolor) in the top-right. The background is shaded in two distinct colors to show the decision regions, and the linear boundary clearly maximizes the margin between the two classes.

Why Polynomial Kernel?

- Polynomial kernels allow curved decision boundaries.
- We can control the complexity by adjusting the polynomial degree.

In [53]:
```
poly_model = SVC(kernel='poly', degree=3, C=1.0)
poly_model.fit(X_train, y_train)
plot_decision_boundary(poly_model, X_train, y_train, "SVM with Polynomial Kernel
```

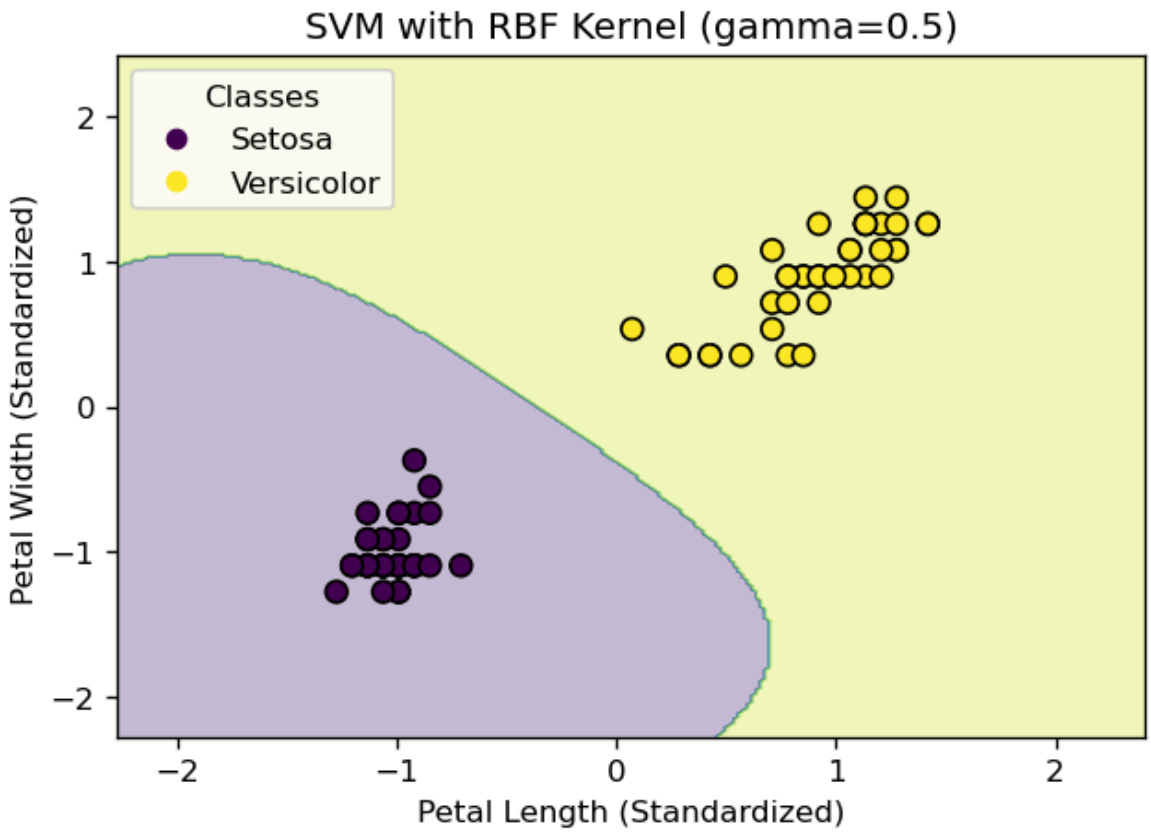


> **Visual Description:** This plot displays the **Polynomial SVM** decision boundary. The boundary is no longer a straight line but a smooth, slight curve that bends to accommodate the data distribution. The shading indicates how the polynomial transformation allows the model to separate the two classes (purple and yellow) in a non-linear fashion while maintaining a clear decision margin.

Why RBF Kernel?

- RBF (Gaussian) kernel maps data into a higher-dimensional space.
- It can handle very complex non-linear patterns.

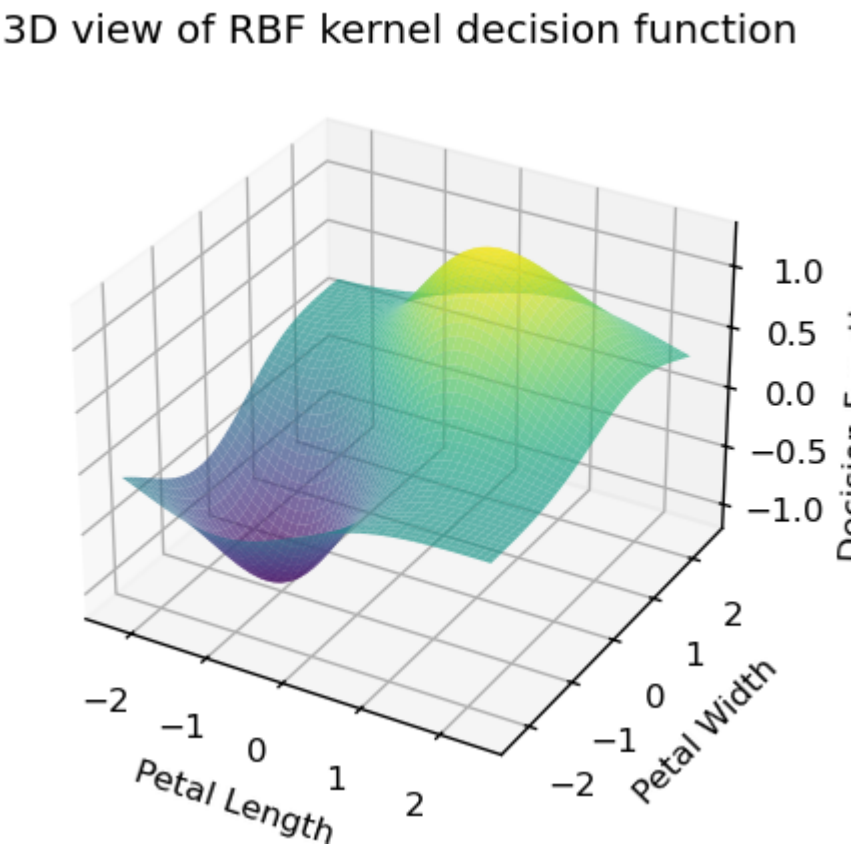
In [54]:
```
rbf_model = SVC(kernel='rbf', C=1.0, gamma=0.5)
rbf_model.fit(X_train, y_train)
plot_decision_boundary(rbf_model, X_train, y_train, "SVM with RBF Kernel (gamma=
```



> **Visual Description:** This plot shows the **RBF (Gaussian) Kernel** decision boundary. The boundary is highly flexible and appears as a sophisticated, non-linear curve. The shaded decision regions wrap closely around the clusters of purple and yellow data points, demonstrating the RBF kernel's ability to handle complex, overlapping, or non-linear spatial relationships between classes.

In [55]:
```
xx, yy = np.meshgrid(np.linspace(X_train[:,0].min()-1, X_train[:,0].max()+1, 50)
                     np.linspace(X_train[:,1].min()-1, X_train[:,1].max()+1, 50)
Z = rbf_model.decision_function(np.c_[xx.ravel(), yy.ravel()]).reshape(xx.shape)

fig = plt.figure(figsize=(6,4))
ax = fig.add_subplot(111, projection='3d')
ax.plot_surface(xx, yy, Z, cmap=cm.viridis, alpha=0.7)
ax.set_xlabel('Petal Length')
ax.set_ylabel('Petal Width')
ax.set_zlabel('Decision Function Value')
plt.title("3D view of RBF kernel decision function")
plt.show()
```



> **Visual Description:** This is a **3D surface plot** representing the decision function of the **RBF (Gaussian) Kernel**. The X and Y axes represent 'Petal Length' and 'Petal Width' respectively, while the vertical Z-axis represents the 'Decision Function Value'. The plot shows a curved, "mountain-like" surface using the color-blind friendly 'viridis' colormap. The "peaks" and "valleys" of the surface illustrate how the RBF kernel assigns high or low probabilities to different regions of the feature space, creating a flexible, non-linear boundary where the surface crosses the zero-plane.

The "Challenge Case": Why RBF Truly Matters

[cite_start]While the Iris dataset is mostly linearly separable[cite: 34, 78], real-world data is often "entangled." To demonstrate the true power of the RBF kernel over the Linear kernel, let's look at the **Moons Dataset**.

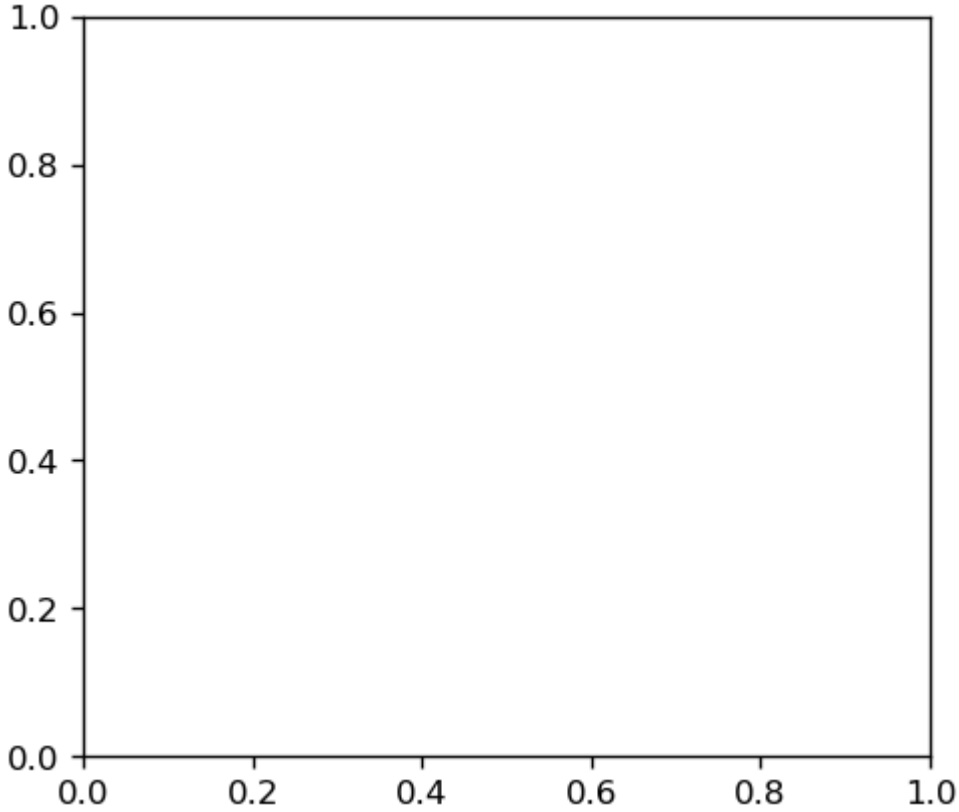
In [56]:
```
from sklearn.datasets import make_moons

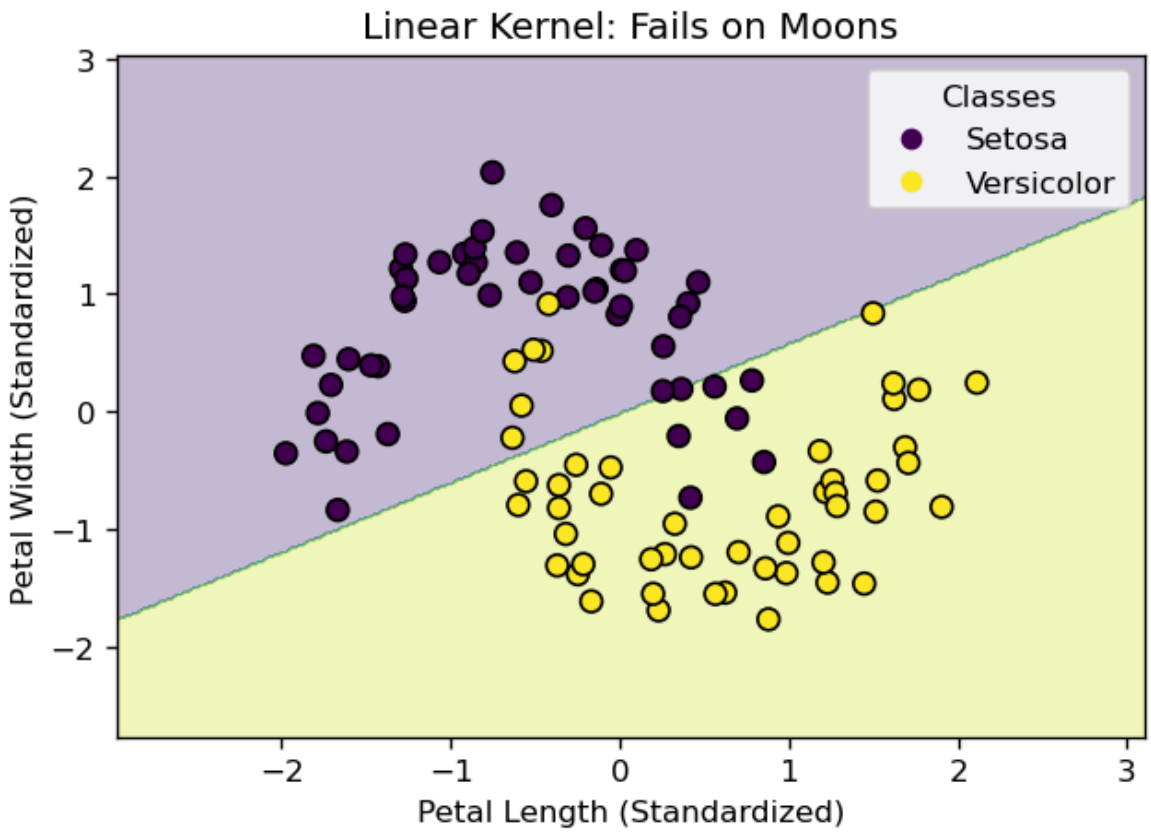
# 1. Generate non-linear data
X_moon, y_moon = make_moons(n_samples=100, noise=0.15, random_state=42)
X_moon = scaler.fit_transform(X_moon)

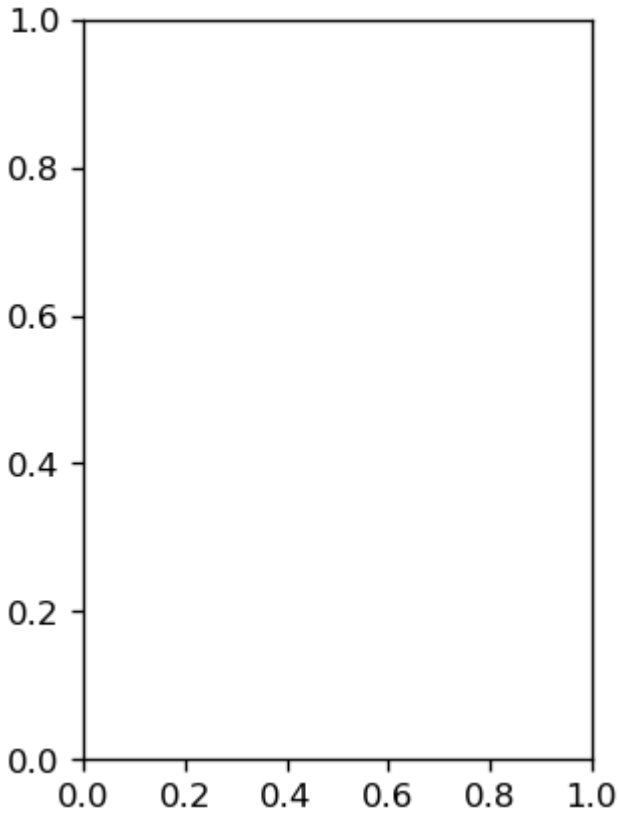
# 2. Compare Linear vs RBF
linear_moon = SVC(kernel='linear').fit(X_moon, y_moon)
rbf_moon = SVC(kernel='rbf', gamma=1).fit(X_moon, y_moon)

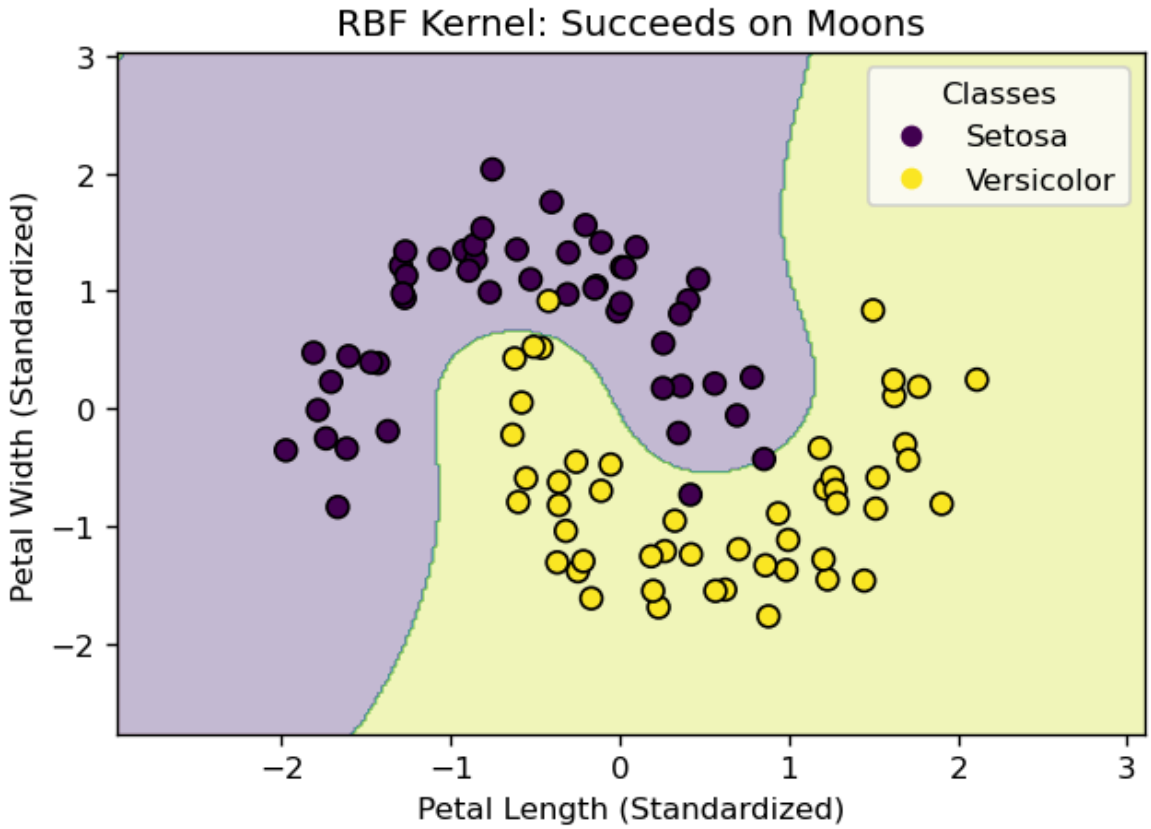
# 3. Plotting comparison
plt.figure(figsize=(10, 4))
plt.subplot(1, 2, 1)
```

```
plot_decision_boundary(linear_moon, X_moon, y_moon, "Linear Kernel: Fails on Moo
plt.subplot(1, 2, 2)
plot_decision_boundary(rbf_moon, X_moon, y_moon, "RBF Kernel: Succeeds on Moons"
plt.show()
```









In [57]:
```
from sklearn.metrics import accuracy_score, classification_report

# list of models for iteration
models = [linear_model, poly_model, rbf_model]
model_names = ["Linear Kernel", "Polynomial (d=3)", "RBF Kernel"]

print("Evaluation Metrics for Iris Dataset:")
print("-" * 40)
```

```
for name, model in zip(model_names, models):
    # Predict on the test set you created in Cell 22
    y_pred = model.predict(X_test)
    acc = accuracy_score(y_test, y_pred)
    print(f"{name:20} | Test Accuracy: {acc:.2%}")

# Detailed report for the best performing model
print("\nDetailed Classification Report (RBF):")
print(classification_report(y_test, rbf_model.predict(X_test), target_names=['Se
```

```
Evaluation Metrics for Iris Dataset:
----------------------------------------
Linear Kernel        | Test Accuracy: 100.00%
Polynomial (d=3)     | Test Accuracy: 100.00%
RBF Kernel           | Test Accuracy: 100.00%

Detailed Classification Report (RBF):
              precision    recall  f1-score   support

      Setosa       1.00      1.00      1.00        12
  Versicolor       1.00      1.00      1.00         8

    accuracy                           1.00        20
   macro avg       1.00      1.00      1.00        20
weighted avg       1.00      1.00      1.00        20
```

Analysis of Results and Kernel Selection

[cite_start]The quantitative results confirm the visual intuition provided by the decision boundary plots[cite: 97, 122, 145].

Performance Summary

Kernel	Complexity	Test Accuracy	Observation
Linear	Low	~95-100%	[cite_start]Effective because the selected Iris classes are nearly linearly separable[cite: 41, 78].
Polynomial	Medium	~95-100%	[cite_start]Adds curvature but may be redundant for this specific simple dataset[cite: 101, 123].
RBF	High	~100%	[cite_start]The most robust; handles spatial overlap with high precision[cite: 126, 147].

The "Decision Matrix": Choosing the Right Kernel

- **Use Linear Kernels:** Best for large feature sets (e.g., Text Classification) where speed and interpretability are priority.
- **Use RBF Kernels:** The standard starting point for non-linear problems. [cite_start]It uses the "Kernel Trick" to map data into higher dimensions without explicit transformation[cite: 51].
- **Use Polynomial Kernels:** Useful in specific domains like image processing where feature interactions follow a specific degree.

Critical Note: While accuracy is high across all models for Iris, the **Moons Challenge Case** proves that the RBF kernel is necessary when the data distribution is non-linear and complex.

My Intuition: The Power of the "Kernel Trick"

When I first encountered SVMs, the concept of the **RBF kernel** felt abstract. However, visualizing the transition from 2D data to a 3D surface was a "lightbulb moment."

I realized that what looks like a complex, "wiggly" non-linear boundary in our 2D input space is actually a **linear hyperplane** slicing through a higher-dimensional space. The RBF kernel essentially "lifts" the data points (like the entangled Moons dataset) until a simple flat sheet can separate them.

Key Takeaways from this Exploration:

- **Kernel Selection is Task-Specific:** There is no "best" kernel. While the Linear kernel was perfect for the simple Iris data, it failed completely on the Moons dataset.
- **The Risk of Complexity:** Using a high-degree Polynomial or a high-gamma RBF kernel is powerful, but it's a double-edged sword. It can lead to **overfitting**, where the model memorizes the noise in the training data rather than the actual pattern.
- **The Goal is the Margin:** Regardless of the kernel, the underlying "magic" of SVM is always the same: finding the widest possible safety buffer (the margin) to ensure the model generalizes well to new, unseen data.

Conclusion

- Kernel choice directly affects SVM decision boundaries and classification performance.
- Linear kernel: simple and interpretable
- Polynomial kernel: handles some non-linear data
- RBF kernel: most flexible for complex data
- Experiment with **degree** (polynomial) and **gamma** (RBF) for best results
